SUBJECT: Several New Characteristics of Probability Crop Acreage Data Collected by the Statistical Reporting Service in Illinois in 1975

TO: Robert Freie, Chief, Methods Staff, ED

THROUGH: William H. Wigton, Head, New Techniques Section, RD

Additional crop acreage data was collected in Illinois in 1975 to be used in concert with LANDSAT data for research purposes. Several new characteristics of the probability data for Illinois were: (1) a time series of direct expansion estimates at four time intervals during the crop season, (2) the follow-up of farmers intentions to plant a crop on a field-by-field basis during the crop season, (3) a measure of acres in field from current aerial photographs (digitized acreage) other than acres reported by the farmer, and (4) the retention of average field sizes by crop type. Information concerning these new characteristics will be presented in this memorandum.

I. Time Series of Direct Expansions

The table of time series of direct expansions is in a memorandum dated April 26, 1976 to Rich Allen of which you received a copy. Major crop results are included in Appendix I.

II. Digitized Acreage

A new source of data collected during the crop season in Illinois was low altitude color infrared aerial photography for a subsample of segments. The photography was developed at a scale approximately five inches to a mile. This current aerial photography provided an accurate high resolution picture of the crops and land uses in late summer for a subsample of 202 segments. Extensive software has been developed by personnel at CAC (Center for Advanced Computation) at the University of Illinois for getting accurate acreage figures for each field in a segment from the photographs. This is accomplished using graphics data tablet digitizing equipment connected to interactive DEC PDP-10 computers in Boston.

The aerial photograph and $7\frac{1}{2}$ minute USGS quadrangle map are placed on the tablet concurrently. A transformation is established from the photograph to the map by digitizing common points. Then all tract and fields boundaries are digitized from the photo and transformed to the latitude-longitude coordinate system of the map. A highly accurate acreage calculation algorithm is then applied to the polygon shaped fields and the acreages are stored on disk files. The original ground file using farmers reported acreage throughout the growing season is also stored on the same storage system. Thus using both files a comparison of expanded acreages using both sources of data is possible. To date, such a comparison has been made for the twenty-nine counties wholly contained in the August 4 LANDSAT Pass in Western Illinois.

Digitized vs. Reported Acreage
As Of August 4, 1975

	Digitized	C.V.	Reported	C.V.
Corn	4,189,587	3.31	4,110,150	3.36
Soybeans	1,578,607	7.76	1,539,212	7.65

The distribution of the difference was not studied on a segment or field basis. When the data for the entire state is available perhaps such an analysis will be performed. If any group is interested in further analysis of this data, the tapes would be available. At the present time, any further analysis is not planned by the New Techniques Section other than the comparison of the two totals after all data for the state is available.

III. Follow-Up of Farmers' Intentions

An added benefit of retaining field level identification was the ability to follow-up farmers' intentions field-by-field. At the request of the Illinois SSO an emphasis was given to soybean intentions and double cropped soybeans after winter wheat.

There were 522 fields on the JES recorded as soybean intentions. Of those 522 fields, 36 actually were planted to soybeans. However, eighty fields that were not recorded soybean intentions on the JES actually went to soybeans. Thus, a net of 44 fields more went to soybeans than expected. Using the average soybean field size and intensive agriculture expansion factor, this amounts to about 200,000 acres or 2% of the soybean estimate.

It is also of interest to note that of the eighty fields that unexpectedly went to soybeans, 42 of the fields were double cropped soybeans after winter wheat which were not recorded as double cropping on the JES.

Included in Appendix III (pages 1-9) is the history of winter wheat fields throughout the crop season and also the history of all fields.

IV. Average Field Sizes

In utilizing LANDSAT data as an auxiliary variable one of the major factors involved is average field size by crop and land use type. There are two major factors involved in the success of estimating a crop once good quality LANDSAT data is obtained. One of these factors is spectral separability of the crop. The other factor is the average field size or amount of data available for estimating mean vectors and covariance matrices of the spectral responses for a crop type. LANDSAT pixels that fall on field boundaries are generally not included in calculating the mean vectors and covariance matrices. Thus crop types with small average field sizes may not have sufficient data for estimation of the multivariate parameters needed for classification.

ing the field level record from the ground surveys it was possible to calculate average field sizes. Appendix II summarizes the average field sizes and also the measure of success in using LANDSAT data described in footnote 1. The segments were treated as a simple random sample in the calculation of average field size.
